

TASMANIAN FUNGI.

By L. RODWAY.

The importance of the study of fungi need not be enlarged upon. Everyone at all acquainted with modern botanical research is aware of the practical importance and great possibilities of this pursuit. In Cooke's Australian Fungi, and subsequently in McAlpine's Systematic Arrangement, we have our fungi up to their date included, but in view of recent numerous additions and probable immediate increase, it is desirable to have a more concise and available list to which new forms may year by year be added.

Had I followed my own inclination, I should have adopted a classification more in accordance with modern ideas, but in the interest of the student I considered it as well not to depart more than necessary from the order used by Cooke. The student must be prepared in this study to find much that is provisional. The subject is so enormous, the proper pursuit of it is so intricate, and the time devoted to it so recent that much incorrectness is permitted to remain until research is more complete. Thus many forms are still maintained as distinct plants when there is almost proof that they are but subordinate forms. This is very common amongst the Uredineæ and Pyrenomycetes, and perhaps almost universal amongst Hyphomycetes and Sphæropsideæ.

There is one plant included here in two forms that might with safety be simplified only for its distinction being still maintained in Europe. It is possible I have been more fortunate than other observers in noting its development.

Lasiosphaeria ovina, Cesati, is a minute globular fungus, about $\frac{1}{50}$ th of an inch diameter, covered with white wool, and growing gregariously on rotting wood. The nucleus of each ascus takes up a position at the apex; the cytoplasm then arranges itself in eight sausage-like masses; in this form it is *L. ovina*, Cesati. In the fulness of time the head of each mass develops a hard dark epispor, or coat, into which the cytoplasm retreats, with the epispor contracting below forming an elliptical spore with, in the young condition, a hyaline tail formed of the unabsorbed membrane-like surface of the sausage-like body. The fungus is then recognised as *Sordaria caudata*, Sace.

There is one new fungus I would record here: *Stephensia varia*, n.s., subterranean, irregularly spherical. Peridium rather thick, sub-cartilaginous. Gleba of one or more broad

contorted hymenial cells or tubes in a pithy fiberoid trama. Ascii narrow, cylindrical. Paraphysis numerous linear. Sporidia spherical, smooth, hyaline, 20 μ . Very variable in size and proportionate development of tubes and trama. When small, $\frac{1}{2}$ - $\frac{3}{4}$ in. tube often single and not very contorted, with copious trama. When about 1 in. tubes fairly numerous, trama reduced, the tuber being then of a firmer consistency. In specimens about 2 in. diameter the tubes are very numerous and large ($\frac{1}{4}$ in.), and trama very slight. These three forms may be persistently distinct, but the ascii and sporidia not differing would lead one to infer they are forms of one plant. The small softer form is much sought by larvæ of small insects, the empty peridium is often found lying on the surface of the soil.

In the following list I have endeavoured to be as brief as possible. Of plants added since the publication of Cooke's Handbook, those described by McAlpine, in or not in conjunction with myself, may be found in Trans. R.S., Vict., Nov. 8th, 1894, or the Bulletin Dept. Agri., New South Wales, Nov., 1895, and Feb., 1896. Those by Massie often with myself, in the new Bulletin, probably in 1897, but the exact date of issue is not yet at my service.

I have included in this list the Mycetozoa, though fully alive to their independence.
